Multiple Logistic Regression Curve: Sampling Effort

Figure 3. Multiple Logistic Regression Curve for Sampling Effort

Interpretation

(note: Sir, I did not go with the habitat route since the graphs are pointing to sampling effort and average distance of observation [and I did not want to overexpound on the habitat types argument as well plus it cannot be directly seen based on the curves and the map])

Based on the generated graphs, the detectability of the Philippine Mouse Deer is influenced by the observation distance and sampling effort. When examining the data for the average distance, there is an inverse relationship between observation distance and species observation; wherein, the higher the distance of observation, the lower the chance of species observation. In terms of the sampling effort data, there is a direct relationship between sampling effort and the probability of species detection; which is seen when higher sampling effort also has a higher species detection rate.
